Abstract

We consider the estimation of the affine parameter (and power-law exponent) in the preferential attachment model with random initial degrees. We derive the likelihood, and show that the maximum likelihood estimator (MLE) is asymptotically normal and efficient. To demonstrate the power of our idea, we present numerical simulations.

Keywords: Preferential Attachment Model, Complex Networks, Statistical Inference, Asymptotic Normality

1. Introduction and Notations

In the past decade random graphs have become well established for modelling complex networks. The *preferential attachment* (PA) model, introduced in [1], is popular in studies of social networks, the world wide web, collaboration
5 networks, and so on. The PA model is a *dynamic* model, in that it describes the evolution of the network through the sequential addition of new nodes, and can explain the so-called *scale-free* phenomenon. This is the observation that in various real world networks the proportion p_k of nodes of degree k follows a power law

$$p_k \propto k^{-\tau},$$

10 for some *power-law exponent* τ . For example, the world wide web is known to have a power-law exponent of approximatively 2 ([2]).

The PA model is built upon the simple paradigm “the rich get richer” and offers a possible scenario in which the Matthew effect (“to all those who have, more will be given”) takes place ([3]). If the network is modelled as a graph, with the vertices representing individuals and the degree of a vertex (the number of outgoing edges) representing wealth, then this means that a new vertex is more likely to connect to already well-connected vertices: vertices with higher degrees (“rich”) inspire more incoming connections (“get richer”).

In the simplest type of PA model this is implemented as follows. For simplicity we do not allow self-loops. We are given a non-decreasing *preferential attachment function* $f: \mathbb{N}^+ \rightarrow \mathbb{R}_+$. The network is initialised at $t = 1$ as a graph consisting of two vertices with one edge between them. Then the recursive attachment scheme begins ($t = 2, 3, \dots$). At time t a new vertex is added to the graph and is connected to exactly one of the t existing vertices, say i , with probability proportional to $f(d_i)$, where d_i is the degree of vertex i in the graph at time $t - 1$. The proportionality, which entails normalising by the sum of all transformed degrees $f(d)$, makes that an *affine* function f can be parametrised without loss of generality by a single parameter δ , in the form $f(k) = k + \delta$, where minimally $\delta > -1$. This special case has been well studied. In particular, it has been established (see e.g. [4, 5]) that the *empirical degree distribution* $(p_k(t))_{k=1}^\infty$, where $p_k(t)$ is the proportion of vertices of degree k in the tree at time t , converges to a limiting degree distribution $(p_k)_{k=1}^\infty$ as $t \rightarrow \infty$, which follows a power law

$$p_k \propto k^{-(3+\delta)}.$$

The Barabási–Albert model is the special case that $\delta = 0$ and has $p_k = 4/(k(k+1)(k+2))$.

If the limiting degree distribution $(p_k)_{k=1}^\infty$ follows a power law, say $p_k = c_k k^{-(3+\delta)}$ with c_k slowly varying in k , then $\log p_k = \log c_k - (3 + \delta) \log k$, where $\log c_k$ behaves like a constant when k is sufficiently large. This suggests that we might estimate δ by performing a linear regression of the logarithm empirical degrees $\log p_k(t)$ with respect to $\log k$, with k sufficiently large. Then $\hat{\delta} := \hat{\tau} - 3$, for $\hat{\tau}$ the negative of slope of the fitted line, should estimate δ . This has been the method of choice in several applications of PA models; see for example the famous paper of [1]. However, this estimator does not work well. One problem is that the equality $\log p_k(n) = \log c_k - \tau \log k$ comes from an asymptotic approximation based on Stirling’s formula, and it is unclear when the asymptotics start to kick in. It is also unclear how to determine the quality of this ad-hoc estimate, by a standard error or confidence interval, or to perform inference.

In the present paper we remedy this by considering the maximum likelihood estimator of δ . We show that this can be easily computed as the solution of an equation, prove its asymptotic normality and derive its standard error. Furthermore, in a simulation study we show that it is quite accurate.

We do this in the following more general context of the *PA model with random initial degrees*. In this model the graph also grows by sequentially adding vertices. However, instead of connecting a new vertex to a single existing

vertex, the vertex at time t comes with a random number m_t edges, which is possibly larger than 1, to connect it to the existing network. The connections are still made according to the basic preferential attachment rule. The special case of this model with each m_t equal to a fixed number $m \in \mathbb{N}$ was well studied (see [5] for a discussion and more references). For $m = 1$ this model reduces to the basic model considered in the preceding paragraphs. However, for real life applications it is somewhat unnatural and inflexible to assume that every vertex comes with the same number of edges, let alone a single edge. In this paper, we allow m_1, m_2, \dots to be an IID sequence of random variables, only restricted to have two finite moments. From the point of view of social network modeling the resulting model can be interpreted as follows. The initial degrees stress the difference of nodes at birth, while the preferential attachment enforces the discrimination against the less well-off individuals (or equivalently the positive discrimination against the well-off individuals). Thus the PA network with random initial degrees combines the effects of “rich-by-birth” and “rich-get-richer”.

The estimation of a preferential attachment function f is of both theoretical and practical interest. Despite that PA networks have been omnipresent in modeling real-world networks, the literature on statistical estimation of this model is sparse. Sound understanding of the statistical properties of PA models will help in evaluating the validity of the PA network model in real-world applications.

The paper [6] proposed an empirical estimator for each $f(k)$ given a general sub-linear preferential attachment function f . Although this estimator was proved to be consistent as $t \rightarrow \infty$, we may expect better estimators if we restrict attention to the domain of affine functions, whose estimation is equivalent to estimating the single parameter δ . A restriction to affine functions is not unnatural, as exactly the affine preferential attachment models correspond to power-law behaviour. Therefore affine f matter most to the practitioners seeking a natural explanation of power laws. The paper [7] solves some statistical problems in the affine model, but focuses on the estimation of the individual degree distribution, and does not directly consider estimating the key affine parameter δ . The present paper provides a ready-to-use solution for estimating the affine parameter, and sound theoretical insight into the statistical modeling of PA networks.

The main challenge in analysing the maximum likelihood estimator of δ is that the model is a non-stationary Markov chain, which continuously visits new states, given by the growing network. This requires careful analysis, but in the end we find that the quantities that are relevant for the estimation of δ stabilise, as the network grows, leading to the desired behaviour of the maximum likelihood estimator. A discovery that is surprising at first is that a snapshot of the network at time n is statistically as informative about δ as observing the full evolution of the network from times $t = 1, 2, \dots, n$. Thus our results apply both to observing a network at a given time (which is likely to be the case in practice) as to observing the evolution of this network up to this time.

The paper is organized as follows. In Section 2 we introduce basic notation

and derive the likelihood and the maximum likelihood estimator. In Section 3 we prove the consistency of this estimator. In Section 4 we derive the main result of the paper, which is the asymptotic normality of the maximum likelihood estimator, by an application of the martingale central limit theorem. To
90 illustrate the results we present simulations in Section 6.

2. Construction of the MLE

We start by introducing the affine preferential attachment model with random initial degree distribution. Here we adapt the notation from [5, 8]. Let
95 $(m_t)_{t \geq 1}$ be an independent and identically distributed (IID) sequence of positive integer-valued random variables. The model produces a network sequence $\{\text{PA}_t(\delta)\}_{t=1}^\infty$, where for every t the network $\text{PA}_t(\delta)$ has a set $V_t = \{v_0, v_1, \dots, v_t\}$ of $t + 1$ vertices and $\sum_{i=1}^t m_i$ edges. The first network $\text{PA}_1(\delta)$ consists of two vertices v_0 and v_1 with m_1 edges between them. For $t \geq 2$, given $\text{PA}_{t-1}(\delta)$, a
100 new vertex v_t is added with m_t edges connecting v_t to V_{t-1} , determined by the *intermediate updating* preferential attachment rule. This updating rule means that the edges are added sequentially using the preferential attachment rule. Define $\text{PA}_{t,0}(\delta) = \text{PA}_{t-1}(\delta)$ to be network after v_{t-1} has been fully integrated, and let $\text{PA}_{t,1}(\delta), \text{PA}_{t,2}(\delta), \dots, \text{PA}_{t,m_t}(\delta)$ be intermediate networks, which add
105 v_t and its m_t edges sequentially to $\text{PA}_{t,0}(\delta)$, as follows. For $1 \leq i \leq m_t$, the network $\text{PA}_{t,i}(\delta)$ is constructed from $\text{PA}_{t,i-1}(\delta)$ by adding an (additional) edge between v_t and a randomly-selected vertex among $\{v_0, v_1, \dots, v_{t-1}\}$. The probability that this is vertex v_j is proportional to $k + \delta$, if $v_j \in V_{t-1}$ has degree k in $\text{PA}_{t,i-1}(\delta)$. Here $\delta > -1$ is an unknown parameter. The random choice is
110 made through a multinomial trial on all the vertices in V_{t-1} . In other words, the conditional probability that the i -th edge of v_t connects it to v_j is

$$\mathbb{P}(v_{t,i} \rightarrow v_j | \text{PA}_{t,i-1}(\delta)) = \frac{\text{Deg}_{t,i-1}(v_j) + \delta}{\sum_{v \in V_{t-1}} (\text{Deg}_{t,i-1}(v) + \delta)}, \quad (1)$$

where $\text{Deg}_{t,i-1}(v)$ is the degree of v in $\text{PA}_{t,i-1}(\delta)$. After all m_t edges have been added to v_t , the network is given by $\text{PA}_{t,m_t}(\delta) = \text{PA}_t(\delta) = \text{PA}_{t+1,0}(\delta)$.

We define $N_k(t)$ to be the number of vertices of degree k in the network
115 $\text{PA}_t(\delta)$ (counting also v_t), and $N_k(t, i - 1)$ to be the number of vertices of degree k in the network $\text{PA}_{t,i-1}(\delta)$, *not counting* v_t (so belonging to V_{t-1}), for $1 \leq i \leq m_t$. By convention $N_k(t, 0) = N_k(t - 1)$. We denote by $D_{t,i}$ the degree of the vertex that was chosen when constructing $\text{PA}_{t,i}(\delta)$ from $\text{PA}_{t,i-1}(\delta)$. So we can say that *the i -th edge chosen by the vertex v_t possesses degree $D_{t,i}$* . For
120 the evolution of the number of vertices of degree k , there are several scenarios. For given natural numbers k and $i \leq m_t$:

- If $D_{t,i} \notin \{k, k - 1\}$, then the number of vertices of degree k remains unchanged, i.e. $N_k(t, i) = N_k(t, i - 1)$.
- If $D_{t,i} = k - 1$, then the vertex that was picked by the incoming vertex
125 gets one extra connection and there is one more vertex of degree k , i.e. $N_k(t, i) = N_k(t, i - 1) + 1$.

- If $D_{t,i} = k$, then the vertex that was picked by the incoming vertex becomes a vertex of degree $k + 1$ and there is one fewer vertex of degree k , i.e. $N_k(t, i) = N_k(t, i - 1) - 1$.

130 After the last update $i = m_t$, the vertex v_t is fully integrated in the network. Since its degree is m_t , we have $N_k(t) = N_k(t, m_t) + 1_{\{k=m_t\}}$. This concludes the time step t and the total number of vertices of the network becomes $t + 1$.

These observations are summarised in the following equation for the degree evolution:

$$N_k(t) = N_k(t - 1) + \sum_{i=1}^{m_t} 1_{\{D_{t,i}=k-1\}} - \sum_{i=1}^{m_t} 1_{\{D_{t,i}=k\}} + 1_{\{k=m_t\}}. \quad (2)$$

135 The total number of edges in $\text{PA}_t(\delta)$ is $M_t := \sum_{j=1}^t m_j$. Clearly the maximal degree in the network $\text{PA}_t(\delta)$ is bounded by M_t , i.e. $N_k(t) = 0$ for any $k > M_t$. Furthermore, $\sum_{k=1}^{m_t} N_k(t) = t + 1$ is the total number of vertices at time t .

The conditional probability of the incoming vertex choosing an existing vertex of degree k to connect to is

$$\mathbb{P}(D_{t,i} = k | \text{PA}_{t,i-1}(\delta), (m_t)_{t \geq 1}) = \frac{(k + \delta)N_k(t, i - 1)}{\sum_{j=1}^{\infty} (j + \delta)N_j(t, i - 1)}. \quad (3)$$

The denominator in this expression counts the “total preference” of all the vertices, and can be written as

$$\begin{aligned} S_{t,i-1}(\delta) &= \sum_{j=1}^{\infty} (j + \delta)N_j(t, i - 1) = \sum_{v \in V_{t-1}} (\text{Deg}_{t,i-1}(v) + \delta) \\ &= t\delta + 2M_{t-1} + 2(i - 1). \end{aligned}$$

140 Abbreviate the degree sequence at time t by $D_t := (D_{t,1}, \dots, D_{t,m_t})$. The conditional likelihood of observing $(D_t)_{t=2}^n = (d_t)_{t=2}^n$ given the edge counts m_1, m_2, \dots is

$$\mathbb{P}((D_t)_{t=2}^n = (d_t)_{t=2}^n | (m_t)_{t \geq 1}) = \prod_{t=2}^n \prod_{i=1}^{m_t} \frac{(d_{t,i} + \delta)N_{d_{t,i}}(t, i - 1)}{S_{t,i-1}(\delta)}. \quad (4)$$

We are interested in estimating δ and assume that the distribution of the edge counts m_t does not contain information on this parameter. As the edge counts are observed, we condition on them throughout, and treat the preceding as the full likelihood of the observation $(D_t)_{t \geq 2}$. In view of (1) the likelihood of observing the full evolution of the network up to $\text{PA}_n(\delta)$ is a function of $(D_t)_{t=2}^n$ and hence the latter vector is statistically sufficient for this full evolution. In the following we shall see that actually observing only the “snapshot” of the network $\text{PA}_n(\delta)$ at time n is already statistically sufficient for δ .

150 Define $N_{>k}(t)$ to be the number of vertices in $\text{PA}_t(\delta)$ of degree (strictly) bigger than k , i.e. $N_{>k}(t) = \sum_{j=k+1}^{t-1} N_j(t)$. As first observed in [6], we have the following lemma. (In [6] the r.h.s. of (5) is called $N_{\rightarrow k}(t)$.)

Lemma 1. *The number of vertices with degree strictly bigger than k is equal to the number of times a vertex of degree k was chosen by the incoming vertices until and including time n plus the number of vertices with initial degrees strictly bigger than k . In other words, if $R_{>k}(n) = 2 \cdot 1_{\{m_1 > k\}} + \sum_{t=2}^n 1_{\{m_t > k\}}$, then*

$$\sum_{t=2}^n \sum_{i=1}^{m_t} 1_{\{D_{t,i}=k\}} = N_{>k}(n) - R_{>k}(n). \quad (5)$$

We introduce the shorthand $D^{(n)} = (D_t)_{t=2}^n$, and from (4) have the log-likelihood function

$$\begin{aligned} l_n(\delta | D^{(n)}) &= \sum_{t=2}^n \sum_{i=1}^{m_t} \left[\log N_{D_{t,i}}(t, i-1) + \log(D_{t,i} + \delta) - \log S_{t,i-1}(\delta) \right] \\ &= \sum_{t=2}^n \sum_{i=1}^{m_t} \log N_{D_{t,i}}(t, i-1) + \sum_{k=1}^{\infty} \log(k + \delta) (N_{>k}(n) - R_{>k}(n)) \\ &\quad - \sum_{t=2}^n \sum_{i=1}^{m_t} \log S_{t,i-1}(\delta). \end{aligned}$$

where the second equality comes from applying Lemma 1 and the fact that

$$\sum_{t=2}^n \sum_{i=1}^{m_t} \log(D_{t,i} + \delta) = \sum_{k=1}^{\infty} \left[\log(k + \delta) \sum_{t=2}^n \sum_{i=1}^{m_t} 1_{\{D_{t,i}=k\}} \right].$$

It follows that the likelihood factorises in a part not involving δ and a part involving δ and the variables $N_{>k}(n)$, given the edge counts (m_t) . Thus by the factorisation theorem (see [9], Corollary 2.6.1) the vector $(N_{>k}(n))_{k \geq 1}$ is statistically sufficient for δ . This vector is completely determined by the network at time n . In particular, observing the network only at time n is sufficient for delta relative to observing its evolution up to and including time n .

For inference on δ we can drop the first term of the log likelihood, which does not depend on δ , and normalize the remaining part by $n+1$ (note that there are $n+1$ vertices in the network at time n). We take the parameter space for δ to be $[-a, b]$, for given numbers $-1 < -a < b < \infty$. The maximum likelihood estimator (MLE) of δ is then given by $\hat{\delta}_n = \operatorname{argmax}_{\delta \in [-a, b]} \iota_n(\delta)$, for

$$\iota_n(\delta) = \sum_{k=1}^{\infty} \log(k + \delta) \frac{N_{>k}(n) - R_{>k}(n)}{n+1} - \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \log S_{t,i-1}(\delta). \quad (6)$$

Provided that the maximum is taken in the interior of the parameter set, the MLE is a solution of the likelihood equation $\iota'_n(\delta) = 0$. This derivative is given by

$$\iota'_n(\delta) = \sum_{k=1}^{\infty} \frac{1}{k + \delta} \frac{N_{>k}(n) - R_{>k}(n)}{n+1} - \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \frac{t}{S_{t,i-1}(\delta)}. \quad (7)$$

3. Consistency

The empirical degree distribution in $\text{PA}_n(\delta)$ is defined as

$$p_k(n) = \frac{N_k(n)}{n+1}.$$

175 In [8] it is shown that this distribution tends to a limit as $n \rightarrow \infty$. Let $(r_k)_{k \geq 1}$ be the probability distribution of the initial degree (and the number of edges added in every step), i.e.

$$r_k = \mathbb{P}(m_1 = k), \quad k \geq 1. \quad (8)$$

Assume that this distribution has finite mean $\mu \geq 1$ and finite second moment $\mu^{(2)}$, and write the shorthand $\theta = 2 + \delta/\mu$. Then the limiting degree distribution 180 $(p_k)_{k \geq 1}$ satisfies the recurrence relation

$$p_k = \frac{k-1+\delta}{\theta} p_{k-1} - \frac{k+\delta}{\theta} p_k + r_k, \quad k \geq 1. \quad (9)$$

Starting from the initial value $p_0 = 0$, we can solve the recurrence relation by

$$p_k = \frac{\theta}{k+\delta+\theta} \sum_{i=0}^{k-1} r_{k-i} \prod_{j=1}^i \frac{k-j+\delta}{k-j+\delta+\theta}, \quad k \geq 1, \quad (10)$$

where the empty product is defined to be 1, should it arise. Because $\sum_{k \geq 1} p_k = \sum_{k \geq 1} r_k = 1$, in view of the recurrence relation (9), the probabilities $(p_k)_{k \geq 1}$ define a proper probability distribution.

185 We list two results on the limiting degree distribution of the preferential attachment model with random initial degrees. See [8] for proofs.

Proposition 2. *If the initial degrees $(m_i)_{i=1}^\infty$ have finite moment of order $1+\varepsilon$ for some $\varepsilon > 0$, then there exists a constant $\gamma \in (0, 1/2)$ such that*

$$\lim_{n \rightarrow \infty} \mathbb{P} \left(\max_{k \geq 1} |p_k(n) - p_k| \geq n^{-\gamma} \right) = 0,$$

where $(p_k)_{k=1}^\infty$ is defined as in (10).

In the case that the initial degree is degenerate, i.e. $r_m = 1$ for some integer $m \geq 1$, the rate of convergence in this result can be improved, and the limiting 190 degree distribution takes a simpler form, as follows.

Proposition 3. *If $r_m = 1$ for some integer $m \geq 1$, then there exists a constant $C > 0$ such that*

$$\lim_{n \rightarrow \infty} \mathbb{P} \left(\max_{k \geq 1} |p_k(n) - p_k| \geq C \sqrt{\log n/n} \right) = 0,$$

where $(p_k)_{k=1}^\infty$ is defined as follows:

$$p_k = \begin{cases} 0, & \text{if } k < m, \\ \frac{\theta \Gamma(k+\delta) \Gamma(m+\delta+\theta)}{\Gamma(m+\delta) \Gamma(k+1+\delta+\theta)}, & \text{if } k \geq m. \end{cases} \quad (11)$$

Furthermore, if $m = 1$, so that $r_1 = 1$, then the empirical degree $p_k(n)$ converges also almost surely to p_k , as $n \rightarrow \infty$, for every k .

Next we give a lemma that will be essential to our analysis later. For a summable sequence $(a_k)_{k \geq 1}$, write $a_{>k} = \sum_{j>k} a_j$.

Lemma 4. *The following recurrence relation holds, with $\theta = 2 + \delta/\mu$,*

$$p_{>k} = \frac{k + \delta}{\theta} p_k + r_{>k}. \quad (12)$$

Proof. We simply sum up terms of (9) and cancel repeated terms. ■

From now on we shall put a superscript (0) to stress that we consider limiting distributions under the true value δ_0 of the parameter. In view of Proposition 2, $N_{>k}(n)/(n+1)$ is asymptotic to $p_{>k}^{(0)}$, while by the Law of Large Numbers $R_{>k}(n)/(n+1)$ tends to $r_{>k}$. Furthermore, for fixed i the sequence $S_{t,i-1}(\delta)/t = \delta + 2\bar{m}_{t-1} + 2(i-1)/t$ is asymptotic to $\delta + 2\mu$, again by the Law of Large Numbers. Therefore, we expect the criterion $\iota'_n(\delta)$ given in (7) to be asymptotic to

$$\iota'(\delta) = \sum_{k=1}^{\infty} \frac{p_{>k}^{(0)} - r_{>k}}{k + \delta} - \frac{1}{2 + \delta/\mu}. \quad (13)$$

Consequently, we expect that the MLE $\hat{\delta}_n$ will be asymptotic to the solution of the equation $\iota'(\delta) = 0$. Because of (12),

$$\iota'(\delta_0) = \sum_{k=1}^{\infty} (p_{>k}^{(0)} - r_{>k}) / (k + \delta_0) - 1 / (2 + \delta_0/\mu) = 0.$$

Thus the true parameter is indeed a solution to this equation. The following lemmas show that this solution is unique.

Define

$$q_k = \frac{p_{>k} - r_{>k}}{\mu} = \frac{(k + \delta)p_k}{2\mu + \delta}. \quad (14)$$

Lemma 5. *For any nonnegative sequence $(v_k)_{k=1}^{\infty}$ that is strictly decreasing with respect to k and any $\delta_1 > \delta_2$, we have*

$$\sum_{k=1}^{\infty} q_k(\delta_1) v_k > \sum_{k=1}^{\infty} q_k(\delta_2) v_k.$$

Proof. We first show that $\sum_{k \geq 1} q_k = 1$. By manipulating the recurrence relation (9), we find

$$\begin{aligned}
\sum_{k=1}^{\infty} q_k &= \frac{1}{2\mu + \delta} \sum_{k=1}^{\infty} (k + \delta) p_k = \frac{1}{2\mu + \delta} \left(\sum_{k=1}^{\infty} k p_k + \delta \right) \\
&= \frac{1}{2\mu + \delta} \left(\sum_{k=1}^{\infty} k \left(\frac{k-1+\delta}{2+\delta/\mu} p_{k-1} - \frac{k+\delta}{2+\delta/\mu} p_k + r_k \right) + \delta \right) \\
&= \frac{1}{2\mu + \delta} \left(\sum_{k=1}^{\infty} k r_k + \sum_{k=1}^{\infty} \frac{k+\delta}{2+\delta/\mu} p_k + \delta \right) \\
&= \frac{1}{2\mu + \delta} \left(\mu + \mu \sum_{k=1}^{\infty} q_k + \delta \right).
\end{aligned}$$

The only solution to this equation for $\sum_k q_k$ has $\sum_k q_k = 1$.

By the recurrence formula (12) and (9), we have $q_k = (k + \delta) p_k / (2\mu + \delta)$, and $q_{k+1} = (k + 1 + \delta)(q_k + r_{k+1}/\mu) / (k + 1 + \delta + 2 + \delta/\mu)$. Therefore the derivative $u_k(\delta) = \frac{d}{d\delta} q_k(\delta)$ satisfies

$$u_{k+1}(\delta) = \frac{2 - (k + 1)/\mu}{(k + 1 + \delta + 2 + \delta/\mu)^2} (q_k(\delta) + r_{k+1}/\mu) + \frac{k + 1 + \delta}{k + 1 + \delta + 2 + \delta/\mu} u_k(\delta).$$

The initial value of this sequence is positive, since

$$u_1(\delta) = \frac{d}{d\delta} q_1(\delta) = \frac{2\mu - 1}{\mu^2(1 + \delta + 2 + \delta/\mu)^2} r_1 > 0.$$

From the recursion it follows that $u_{k+1}(\delta)$ remains positive at least as long as $k + 1 \leq 2\mu$. For $k + 1 > 2\mu$ the first term of the recursion is negative, while the second term has the sign of $u_k(\delta)$. From the fact that $\sum_k q_k(\delta) = 1$ for every δ , it follows that $\sum_k u_k(\delta) = 0$, and hence $u_k(\delta)$ cannot remain positive indefinitely. If $K(\delta) + 1$ is the first k for which $u_k(\delta) < 0$, then it must be that $K(\delta) + 1 > 2\mu$, which implies that $u_k(\delta) < 0$ for every $k > K(\delta) + 1$ as well. Since v_k is decreasing it follows that

$$\sum_k v_k u_k(\delta) > \sum_{k \leq K(\delta)} v_{K(\delta)} u_k(\delta) + \sum_{k > K(\delta)} v_{K(\delta)} u_k(\delta) = v_{K(\delta)} 0 = 0.$$

210 Integrating this over the interval $[\delta_1, \delta_2]$ gives the assertion. ■

Lemma 6. *The function $\delta \mapsto \iota'(\delta)$ possesses a unique zero at $\delta = \delta_0$. It is positive for $\delta < \delta_0$ and negative if $\delta > \delta_0$.*

Proof. Following the definition (13) of ι' it was seen that δ_0 is a zero. Fix some $\delta \neq \delta_0$. Since $1 = \sum_k p_k(\delta)$ and $q_k(\delta) = (k + \delta) p_k(\delta) / (2\mu + \delta)$, we can rewrite

$\iota'(\delta)$ as

$$\begin{aligned}\iota'(\delta) &= \sum_{k=1}^{\infty} \frac{\mu q_k^{(0)}}{k + \delta} - \frac{1}{2 + \delta/\mu} \\ &= \sum_{k=1}^{\infty} \frac{\mu q_k^{(0)}}{k + \delta} - \sum_{k=1}^{\infty} \frac{(k + \delta)p_k(\delta)}{(k + \delta)(2 + \delta/\mu)} \\ &= \sum_{k=1}^{\infty} \frac{\mu q_k^{(0)}}{k + \delta} - \sum_{k=1}^{\infty} \frac{\mu q_k(\delta)}{k + \delta}.\end{aligned}$$

Applying Lemma 5 with $v_k = 1/(k + \delta)$, we see that $\iota'(\delta) > 0$ when $\delta < \delta_0$, and $\iota'(\delta) < 0$ when $\delta > \delta_0$. ■

215 The proof of consistency of the MLE will be based on uniform convergence of ι'_n to ι' , together with the uniqueness of the zero of ι' . For the convergence, and also for the proof of asymptotic normality, we need the following lemma.

Lemma 7 (Cesàro convergence for random variables). *Let $(X_t)_{t \in \mathbb{N}}$ be a sequence of random variables, $(a_t)_{t \in \mathbb{N}}$ a sequence of numbers, X and a a random variable and number, and let \bar{X}_t and \bar{a}_t be the average of the first t variables or numbers, respectively.*

- i). *If $X_t \xrightarrow{a.s.} X$, then $\bar{X}_t \xrightarrow{a.s.} X$.*
- ii). *If $X_t \xrightarrow{L_1} X$, or equivalently $X_t \xrightarrow{P} X$ and $(X_t)_{t \in \mathbb{N}}$ is uniformly integrable, then $\bar{X}_t \xrightarrow{L_1} X$.*
- 225 iii). *If $X_t \xrightarrow{L_1} X$ and $\bar{a}_t \rightarrow a$ and $|\bar{a}|_t = O(1)$, then $(\bar{aX})_t \xrightarrow{L_1} aX$.*

Proof. Statement (i) is the usual Cesàro convergence, applied to almost every of the deterministic sequences $X_t(\omega)$ obtained for elements ω of the underlying probability space.

Statement (ii) is the special case of (iii) with $a_t = 1$, for every t .

To prove statement (iii) we decompose

$$\begin{aligned}|\overline{(aX)}_t - aX| &= \left| \frac{1}{t} \sum_{i=1}^t a_i X_i - \frac{1}{t} \sum_{i=1}^t a_i X + \frac{1}{t} \sum_{i=1}^t a_i X - aX \right| \\ &\leq \frac{1}{t} \sum_{i=1}^K |a_i(X_i - X)| + \frac{1}{t} \sum_{i=K+1}^t |a_i(X_i - X)| + |X| |\bar{a}_t - a|.\end{aligned}$$

Take the expectation across to bound the expected value of the left side by

$$\frac{K}{t} \max_{1 \leq i \leq K} |a_i| \max_t \mathbb{E}|X_t - X| + |\bar{a}|_t \max_{K < i \leq t} \mathbb{E}|X_i - X| + |\bar{a}_t - a| \mathbb{E}|X|.$$

230 Because $\mathbb{E}|X_i - X| \rightarrow 0$ as $i \rightarrow \infty$, for any $\varepsilon > 0$, there exists K such that $\sup_{i > K} \mathbb{E}|X_i - X| < \varepsilon$. Then the second term is bounded above by a constant

times ε , by the assumption on $\overline{|a|}_t$. For fixed K the first and third terms tend to zero as $t \rightarrow \infty$. Thus the limsup as $t \rightarrow \infty$ of the whole expression is bounded by a multiple of ε , for every $\varepsilon > 0$. ■

Lemma 8. *The derivative ι'_n of the log-likelihood function converges uniformly to the limiting criterion ι' , i.e. as $n \rightarrow \infty$ for every $\epsilon > 0$,*

$$\sup_{\delta > -1+\epsilon} |\iota'_n(\delta) - \iota'(\delta)| \xrightarrow{P} 0.$$

235

Proof. For $r_{>k}(n) = R_{>k}(n)/(n+1)$, the difference $\iota'_n(\delta) - \iota'(\delta)$ can be decomposed as

$$\sum_{k=1}^{\infty} \frac{p_{>k}(n) - p_{>k}^{(0)}}{k + \delta} + \sum_{k=1}^{\infty} \frac{r_{>k}(n) - r_{>k}}{k + \delta} + \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \frac{t}{S_{t,i-1}(\delta)} - \frac{\mu}{2\mu + \delta}.$$

We deal with the first two terms and the difference of the last two terms separately.

As $kN_{>k}(n) \leq 2M_n$, where $M_n = \sum_{t=1}^n m_t$ is the total number of edges in $\text{PA}_n(\delta)$, we have $p_{>k}(n) \leq 2\overline{m}_n/k$, for every k . Hence, for $\delta \geq -\eta := -1 + \epsilon$,

$$\sum_{k=1}^{\infty} \frac{|p_{>k}(n) - p_{>k}^{(0)}|}{k + \delta} \leq \sum_{k \leq K} \frac{|p_{>k}(n) - p_{>k}^{(0)}|}{k - \eta} + \sum_{k > K} \frac{2\overline{m}_n}{k(k - \eta)} + \sum_{k > K} \frac{p_{>k}^{(0)}}{k - \eta}.$$

Since $\overline{m}_n \rightarrow \mu$ almost surely, by the Law of Large Numbers, the second term on the right side can be made arbitrarily small by choice of K . The same is true for the third term. For any fixed K the first term converges in probability to 0 as $n \rightarrow \infty$, by Proposition 2. Thus the full expression tends to zero.

The variable $r_{>k}(n) - r_{>k}$ can be written in the form $2(1_{m_1 > k} - r_{>k})/(n+1) + \sum_{t=2}^n (1_{m_t > k} - r_{>k})/(n+1)$. This is a weighted sum of independent centered Bernoulli variables with success probability $r_{>k}$. Its first absolute moment can be bounded by its standard deviation and is bounded by a multiple of the root of $r_{>k}(1 - r_{>k})/(n+1)$. It follows that the supremum over $\delta > -\eta = -1 + \epsilon$ of the absolute value of the second term has expected value bounded above by a multiple of

$$\frac{1}{\sqrt{n+1}} \sum_{k=1}^{\infty} \frac{\sqrt{r_{>k}(1 - r_{>k})}}{k - \eta}.$$

Since $r_{>k} \leq k^{-1}\mu$, by Markov's inequality, the series converges easily, and the expression tends to zero as $n \rightarrow \infty$.

With slight abuse of notation write $\overline{m}_n = \sum_{t=1}^n m_t/(n+1)$. The third term

240

can be decomposed as

$$\begin{aligned}
& \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \left[\frac{1}{S_{t,i-1}(\delta)/t} - \frac{1}{\delta + 2\bar{m}_{t-1}} \right] \\
& + \frac{1}{n+1} \sum_{t=2}^n \left[\frac{m_t}{\delta + 2\bar{m}_{t-1}} - \frac{m_t}{2\mu + \delta} \right] + \left[\frac{1}{n+1} \sum_{t=2}^n \frac{m_t}{2\mu + \delta} - \frac{\mu}{2\mu + \delta} \right] \\
& = \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \frac{2(i-1)/t}{(\delta + 2\bar{m}_{t-1} + 2(i-1)/t)(\delta + 2\bar{m}_{t-1})} \\
& + \frac{1}{n+1} \sum_{t=2}^n \frac{m_t(2\mu - 2\bar{m}_{t-1})}{(\delta + 2\bar{m}_{t-1})(2\mu + \delta)} + \frac{\bar{m}_n - \mu}{2\mu + \delta}.
\end{aligned}$$

The supremum over $\delta > -\eta$ of the absolute value of this expression is bounded above by

$$\frac{1}{n+1} \sum_{t=2}^n \frac{m_t^2/t}{(2\bar{m}_{t-1} - \eta)^2} + \frac{1}{n+1} \sum_{t=2}^n \frac{m_t 2|\mu - \bar{m}_{t-1}|}{(2\bar{m}_{t-1} - \eta)(2\mu - \eta)} + \frac{|\bar{m}_n - \mu|}{2\mu - \eta}.$$

The third term tends to zero almost surely by the Law of Large Numbers. In the first term we have that the variables $X_t := t^{-1}/(2\bar{m}_{t-1} - \eta)^2$ converge almost surely to 0 as $t \rightarrow \infty$, while the averages of the variables $a_t := m_t^2$ tend to $\mu^{(2)}$ almost surely, again by the Law of Large Numbers. Applying Lemma 7 to the sequences of *numbers* $X_t(\omega)$ and $a_t(\omega)$ obtained by selecting ω from the underlying probability space so that both convergences are valid, we see that the first term tends to zero, for such ω , and hence almost surely. The second term tends to zero by the same argument, now with the choice $X_t := 2|\mu - \bar{m}_{t-1}|/((2\bar{m}_{t-1} - \eta)(2\mu - \eta))$.

■

Combining the two preceding lemmas gives the following theorem.

Theorem 9. *The MLE $\hat{\delta}_n$ is consistent: $\hat{\delta}_n \rightarrow \delta_0$, in probability under δ_0 , for every $\delta_0 \in (-a, b)$.*

Proof. Because ι' is continuous on $[-a, b]$ and vanishes only at δ_0 , we have that $\inf_{\delta \in [-a, b]: |\delta - \delta_0| > \epsilon} |\iota'(\delta)| > 0$, for every ϵ . More precisely, by Lemma 6 it is bounded away from zero in the positive direction for $\delta < \delta_0 - \epsilon$ and in the negative direction if $\delta > \delta_0 + \epsilon$. Since ι'_n tends uniformly to ι , by Lemma 8, the same is true for ι'_n , with probability tending to one. This shows that the maximum of ι_n must be contained in $[\delta_0 - \epsilon, \delta_0 + \epsilon]$, with probability tending to one. ■

4. Asymptotic Normality

We shall apply the following martingale central limit theorem (see Corollary 3.1 in [10] or Theorem XIII.1.1 in [11]) to study the asymptotic normality

of the MLE. The triangular array version with $k_n \rightarrow \infty$ given here is equivalent to the theorem in the latter reference (stated for $k_n = n$), as remarked preceding its statement on page 171.

Proposition 10. *Suppose that for every $n \in \mathbb{N}$ and $k_n \rightarrow \infty$ the sequence $X_{n,1}, \dots, X_{n,k_n}$ are martingale differences relative to an arbitrary filtrations $\mathcal{F}_{n,1} \subset \mathcal{F}_{n,2} \subset \dots \subset \mathcal{F}_{n,k_n}$. If $\sum_{i=1}^{k_n} \mathbb{E}[X_{n,i}^2 | \mathcal{F}_{n,i-1}] \xrightarrow{P} v$ for a positive constant v , and*

$$\sum_{i=1}^{k_n} \mathbb{E}[X_{n,i}^2 1_{\{|X_{n,i}| > \varepsilon\}} | \mathcal{F}_{n,i-1}] \xrightarrow{P} 0,$$

270 *for every $\varepsilon > 0$, then $\sum_{i=1}^{k_n} X_{n,i} \rightsquigarrow N(0, v)$.*

Lemma 11. *Given almost every sequence $(m_t)_{t=1}^\infty$ we have, under δ_0 ,*

$$\sqrt{n}(\iota'_n(\delta_0) - \iota'(\delta_0)) \rightsquigarrow N(0, \nu_0), \quad (15)$$

where $\iota'(\delta_0) = 0$ and

$$\nu_0 = \sum_{k=1}^{\infty} \frac{\mu q_k^{(0)}}{(k + \delta_0)^2} - \frac{\mu}{(2\mu + \delta_0)^2}.$$

Proof. Throughout the proof we condition on $(m_t)_{t=1}^\infty$, without letting this show up in the notation.

We can write

$$\iota'_n(\delta_0) = \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} Y_{t,i},$$

for

$$Y_{t,i} = \frac{1}{D_{t,i} + \delta_0} - \frac{t}{S_{t,i-1}(\delta_0)} = \frac{1}{D_{t,i} + \delta_0} - \frac{1}{\delta_0 + \bar{m}_{t-1} + 2(i-1)/t}.$$

As to be expected from the fact that they are score functions, the variables $Y_{2,1}, Y_{2,2}, \dots, Y_{2,m_2}, Y_{3,1}, \dots, Y_{3,m_3}, Y_{4,1}, \dots$ are martingale differences relative to the filtration $\mathcal{F}_{2,1} \subset \mathcal{F}_{2,2} \subset \dots \subset \mathcal{F}_{2,m_2} \subset \mathcal{F}_{3,1} \subset \dots \subset \mathcal{F}_{3,m_3} \subset \mathcal{F}_{4,1} \subset \dots$ obtained by letting $\mathcal{F}_{t,i}$ correspond to observing the evolution of the PA graph up to $\text{PA}_{t,i}(\delta)$. Indeed, in view of (3),

$$\mathbb{E}[Y_{t,i} | \mathcal{F}_{t,i-1}] = \sum_{k=1}^{\infty} \frac{1}{k + \delta_0} \frac{N_k(t, i-1)(k + \delta_0)}{S_{t,i-1}(\delta_0)} - \frac{t}{S_{t,i-1}(\delta_0)} = 0,$$

275 since $\sum_k N_k(t, i-1) = t$ is the number of vertices in the graph at time t , for every i (not counting v_t). (Set $\mathcal{F}_{t,0} = \mathcal{F}_{t-1,m_{t-1}}$.)

We now apply Proposition 10 to the triangular array of martingale differences $X_{2,1}, \dots, X_{n,m_n}$, for $n = 1, 2, \dots$, and $X_{t,i} = Y_{t,i}/\sqrt{n+1}$. The n -th row

possesses $M_n = \sum_{t=2}^n m_t \rightarrow \infty$ variables. Since the variables $Y_{t,i}$ are uniformly bounded by $2/(1+\delta_0)$, the Lindeberg condition, in the display of Proposition 10, is trivially satisfied. We need to show that

$$\frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \mathbb{E}[Y_{t,i}^2 | \mathcal{F}_{t,i-1}] \xrightarrow{P} \nu_0.$$

In view of (3),

$$\begin{aligned} \mathbb{E}[Y_{t,i}^2 | \mathcal{F}_{t,i-1}] &= \mathbb{E}\left[\frac{1}{(D_{t,i} + \delta_0)^2} | \mathcal{F}_{t,i-1}\right] - \left(\frac{t}{S_{t,i-1}(\delta_0)}\right)^2 \\ &= \sum_{k=1}^{\infty} \frac{1}{(k + \delta_0)^2} \frac{N_k(t, i-1)(k + \delta_0)}{S_{t,i-1}(\delta_0)} - \left(\frac{t}{S_{t,i-1}(\delta_0)}\right)^2. \end{aligned}$$

Since i edges are added when constructing $\text{PA}_{t,i}(\delta)$ from $\text{PA}_{t,0}(\delta)$, the number of nodes of degree k cannot change by more than $i \leq m_t$. Therefore, for every t ,

$$\max_{1 \leq i \leq m_t} \left| \frac{N_k(t, i-1)}{t} - \frac{N_k(t, 0)}{t} \right| \leq \frac{m_t}{t}.$$

Since m_t has finite second moment, we have $\sum_t \mathbb{P}(m_t > t\epsilon) < \infty$, for every $\epsilon > 0$, and hence $m_t/t \rightarrow 0$, almost surely, as $t \rightarrow \infty$. We combine this with the preceding display and Proposition 2 to see that $N_k(t, i-1)/t \rightarrow p_k^{(0)}$ in probability, as $t \rightarrow \infty$, for every fixed k , uniformly in $1 \leq i \leq m_t$. As a function of k , the numbers $N_k(t, i-1)/t$ are a probability distribution on \mathbb{N} , and hence $\sum_k |N_k(t, i-1)/t - p_k^{(0)}| \rightarrow 0$, by Scheffe's theorem, uniformly in $1 \leq i \leq m_t$. In particular, the $N_k(t, i-1)/t$ are uniformly integrable (summable), whence by the dominated convergence theorem also, uniformly in $1 \leq i \leq m_t$, as $t \rightarrow \infty$,

$$\sum_k \left| \frac{N_k(t, i-1)/t}{k + \delta_0} - \frac{p_k^{(0)}}{k + \delta_0} \right| \xrightarrow{P} 0.$$

By the definition of $S_{t,i-1}(\delta_0)$, we also have

$$\max_{1 \leq i \leq m_t} \left| \frac{S_{t,i-1}(\delta_0)}{t} - (\delta + 2\bar{m}_{t-1}) \right| \leq \frac{2m_t}{t}.$$

Therefore, by the Law of Large Numbers we obtain that $S_{t,i-1}(\delta_0)/t \rightarrow (\delta_0 + 2\mu)$, almost surely, uniformly in $1 \leq i \leq m_t$.

Combining the preceding we see that, for almost every sequence (m_t) ,

$$\frac{1}{m_t} \sum_{i=1}^{m_t} \sum_k \frac{N_k(t, i-1)}{(k + \delta_0) S_{t,i-1}(\delta_0)} \xrightarrow{P} \sum_k \frac{p_k^{(0)}}{(k + \delta_0)(\delta_0 + 2\mu)}.$$

Next by Lemma 7, applied with X_t equal to the left side of the preceding display (which is bounded and hence uniformly integrable) and $a_t = m_t$, we see that,

for almost every sequence (m_t) ,

$$\frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \sum_{k=1}^{\infty} \frac{N_k(t, i-1)}{(k+\delta_0)S_{t,i-1}(\delta_0)} \xrightarrow{P} \mu \sum_k \frac{p_k^{(0)}}{(k+\delta_0)(\delta_0+2\mu)}$$

By a similar, but simpler, argument we see that

$$\frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \left(\frac{t}{S_{t,i-1}(\delta_0)} \right)^2 \rightarrow \frac{\mu}{(\delta_0+2\mu)^2}.$$

Since $p_k^{(0)}/(2\mu+\delta_0) = q_k^{(0)}/(k+\delta_0)$ by (14), the difference of the right sides of the last two displays is ν_0 . ■

The following is the main result of the paper.

Theorem 12. *If δ_0 is interior to the parameter set, then the MLE $\hat{\delta}_N$ satisfies, for ν_0 given in Lemma 11,*

$$\sqrt{n}(\hat{\delta}_n - \delta_0) \rightsquigarrow N(0, \nu_0^{-1}). \quad (16)$$

Proof. By Theorem 9 $\hat{\delta}_n$ tends to δ_0 , hence is with probability tending to one interior to the parameter set, and must solve the likelihood equation $\iota'_n(\hat{\delta}_n) = 0$. By Taylor expansion there exists $\tilde{\delta}_n$ between δ_0 and $\hat{\delta}_n$ such that

$$0 = \iota'_n(\hat{\delta}_n) = \iota'_n(\delta_0) + \iota''_n(\tilde{\delta}_n)(\hat{\delta}_n - \delta_0).$$

Using that $\iota'(\delta_0) = 0$, we can reformulate the preceding display as

$$\sqrt{n}(\hat{\delta}_n - \delta_0)\iota''_n(\tilde{\delta}_n) = -\sqrt{n}(\iota'_n(\delta_0) - \iota'(\delta_0)).$$

The expression on the right is studied in Proposition 11, and seen to converge in distribution to $N(0, \nu_0)$.

The second derivative takes the form

$$\iota''_n(\delta) = - \sum_{k=1}^{\infty} \frac{1}{(k+\delta)^2} \frac{N_{>k}(n) - R_{>k}(n)}{n+1} + \frac{1}{n+1} \sum_{t=2}^n \sum_{i=1}^{m_t} \frac{t^2}{S_{t,i-1}^2(\delta)}.$$

By a similar argument as in the proof of Lemma 8 we see that this converges in probability to the second derivative $\iota''(\delta)$, uniformly in δ in a neighbourhood of δ_0 . Since $\tilde{\delta}_n \rightarrow \delta_0$ in probability and ι'' is continuous, it follows that $\iota''_n(\tilde{\delta}_n) \rightarrow \iota''(\delta_0)$. The latter limit is given by

$$\iota''(\delta_0) = - \sum_{k=1}^{\infty} \frac{p_{>k}^{(0)} - r_{>k}}{(k+\delta_0)^2} + \frac{\mu^2}{2\mu+\delta} = -\nu_0,$$

by (14). An application of Slutsky's lemma concludes the proof. ■

It is shown in the preceding proof that the *observed information* $-\iota_n''(\hat{\delta}_n)$ is a consistent estimator of the inverse asymptotic variance ν_0 . Thus, for ξ_α quantiles from the normal distribution,

$$\hat{\delta}_n \pm \xi_\alpha / \sqrt{-n\iota_n''(\hat{\delta}_n)}$$

is a confidence interval for δ .

5. Local Asymptotic Normality and Efficiency

The maximum likelihood estimator is well known to be asymptotically efficient, for instance in the sense of being *locally asymptotic minimax*, if the model is locally asymptotically normal and the distributional limit is reached locally uniformly in the parameter. See e.g. Chapters 7 and 8 in [12]. Local uniform convergence of $\hat{\delta}_n$ can be proved by a slight strengthening of Theorem 12: consider the behaviour under every sequence of parameters $\delta_0 + h/\sqrt{n}$, for $h \in \mathbb{R}$, instead of only under δ_0 .

Local asymptotic normality entails a quadratic expansion of the local log likelihood ratio, given by, for given $h \in \mathbb{R}$,

$$\log \frac{l_n(\delta_0 + h/\sqrt{n} | D^{(n)})}{l_n(\delta_0 | D^{(n)})}.$$

In view of (6) this can be written in the form

$$(n+1)[\iota_n(\delta_0 + h/\sqrt{n}) - \iota_n(\delta_0)] = \frac{n+1}{\sqrt{n}} h \iota_n'(\delta_0) + \frac{1}{2} \frac{n+1}{n} h^2 \iota_n''(\tilde{\delta}_n),$$

for $\tilde{\delta}_n$ between δ_0 and $\delta_0 + h/\sqrt{n}$. By Lemma 11 the first term on the right tends under δ_0 to h times a centered normal variable with variance ν_0 . The second term on the right tends in probability to $-h^2/2\nu_0$, by the same arguments as in the proof of Theorem 12.

This establishes the local asymptotic normality for our experiment and hence the efficiency of the MLE.

6. Simulation Study

In this section we demonstrate the power of the MLE by applying it in the setting of the famous paper [1]. We show that the MLE provides a better estimate for the power-law exponent than the ad-hoc estimator in this paper, and conclude that it is more informative about the limiting degree distribution than the empirical degree distribution. We also offer an explanation for this somewhat counter-intuitive phenomenon.

6.1. “On the shoulder of the giants”

315 We present our simulation results to pay tribute to [1], who considered (only) the so-called linear preferential attachment model, i.e. $\delta_0 = 0$ (or $f(k) = k$). In this case the limiting degree distribution can be explicitly given as $p_k = 6/(k(k+1)(k+2))$. Figure 2 of [1] presented a simulation of 150,000 vertices with fixed number of edges $m = 5$ and true parameter $\delta_0 = 0$. Fitting a
320 straight line to the log empirical degree against the log degree gave a slope 2.9, which suggests a parameter δ equal to $2.9 - 3 = -0.1$, different from the true value $\delta_0 = 0$. Below we show that the MLE gives an estimate of δ with a much smaller error, and show that the sample mean and variance of the MLE are close to the asymptotic values obtained in Theorem 12. Since the most important
325 characteristic of the limiting degree distribution is its power-law exponent τ , which depends on δ through the relation $\tau = 3 + \delta$, the MLE in turn also gives a better insight in the limiting degree distribution.

As mentioned in Section 1 a practical problem of fitting a straight line to the plot of the log empirical degree $\log p_k(n)$ against $\log k$, is that the variance
330 of the former blows up with increasing degree k . This makes a careful choice of the cutoff mandatory, but difficult, as is illustrated in Figure 1, which is an independent replicate of Figure 2(A) of [1]. Actually, in our simulations we found it to be non-trivial to obtain the estimate 2.9 of the negative of the slope (as found in [1]). In contrast, the MLE implicitly weighs the information in the
335 various degrees, and automatically yields accurate estimates.

We studied the sampling distribution of the MLE by generating 3,500 independent replicates of the linear PA graph, and computing $\hat{\delta}$ for each replicate. A histogram of the 3,500 estimates $\hat{\delta}$ is plotted in Figure 2, and numerical summaries are given in Table 1. We compared these to the asymptotic distribution
340 given in Theorem 12, and a “best fitting” normal distribution with mean and variance taken equal to the sample mean and variance of the 3,500 replicates. Inspection of Figure 2 and Table 1 gives the following observations.

- The MLE is very accurate. In 3,500 replicates the *worst* estimate deviated about 0.06 from the truth $\delta_0 = 0$ (Table 1), better than the error $2.9 - 3 = -0.1$ obtained in [1].
345
- The bias of the MLE is estimated at about 0.00082 and the variance at 0.00033 (Table 1, “Mean” and “Samp. Var”), showing that the bias gives a negligible contribution to the mean square error, as predicted by Theorem 12. The estimated variance is remarkably close to the asymptotic variance predicted by Theorem 12 (given in the column “Pred. Var.” of
350 Table 1).
- From the relation $\tau = 3 + \delta$ we obtain the sample bias and variance in the estimates of the power-law exponent.
- The sampling distribution of $\hat{\delta}_n$ with $n = 150,000$ and fixed $m = 5$ is quite close to a normal distribution (Figure 2), although it appears slightly
355 skewed to the right.

- The normal law that fits best to the sampling distribution is very close to the asymptotic normal distribution (red and blue curves in Figure 2).

Figure 1: Plot of \log Empirical Degree $p_k(n)$ (vertical axis) versus \log degree $\log k$ of in one simulation of a Linear Preferential Attachment graph with $m = 5$ and $n = 150,000$.

Min.	Median	Mean	Max.	Samp. Var.	Pred. Var.
-0.064580	0.0013350	0.0008268	0.064090	0.00033715	0.00033594

Table 1: Summary of 3,500 replicates of the MLE in the linear Preferential Attachment model with $m = 5$ and $n = 150,000$. “Pred. Var.” gives the variance as predicted by the asymptotic distribution of the MLE.

6.2. “The majority rules”

360 As we pointed out in the previous section, the MLE offers more information about the limiting degree distribution than the empirical degree distribution. We offer a possible explanation why this happens. If we only utilize the empirical degree distribution and try to fit a power-law, then *essentially* we must restrict ourselves to nodes with high degrees, and neglect the absolute majority with
365 low degrees. However if the universal mechanism of preferential attachment is responsible for the evolution of the whole network, then this mechanism is also responsible for the nodes with low degrees, whence nodes with low degrees also

Figure 2: Histogram of 3,500 replicates of the MLE in the Linear Preferential Attachment model with $m = 5$ and $n = 150,000$.

provide information about the underlying mechanism. The MLE takes account of all the nodes, and also weighs their relevance in an automated manner, and
 370 uses more information than present in just nodes of high degrees. In this sense, the majority (the nodes with low degrees) wins over the minority (the nodes with high degrees) and thus “rules”.

7. Acknowledgements

The paper is partially inspired by one author’s master’s thesis project ([13]),
 375 where the modeling of the movie-actor network with the preferential attachment models was studied.
